Abstract

Cold Target Recoil Ion Momentum Spectroscopy allows the detection of the three-dimensional momentum vector of the recoiling product ion from ion, electron or photon atom collisions with 4π solid angle and high resolution. It can be combined with large area position-sensitive detectors for electron detection or measurement of the projectile charge-state and scattering angle. Such 'reaction microscopes' cover the full correlated momentum space of all fragments of an atomic reaction yielding kinematically complete information for each reaction event. For the first time in atomic collision physics fully differential data became available in the sense that not only the momenta of all fragments, but also the complete momentum space is observed in one experiment. Recent results achieved with this new technique for slow p–He collisions and threshold photo ionization of He will be discussed.

1. Outline of COLTRIMS

With the development of new experimental techniques which exploit large area position-sensitive detectors and time-of-flight measurements for the coincident detection of the reaction products of an atomic collision, it recently has become possible to perform fully differential experiments. Such experiments result in kinematically complete information on the reaction under investigation. They yield multidimensional images of the square of the correlated final state wavefunction and the most complete and detailed information achievable for a continuum state if one neglects the spin. Recoil-ion momentum spectroscopy is the key technology in this rapid development. It allows determination of the charge-state and the three-dimensional momentum vector of the ions of an atomic reaction with a unique combination of high resolution and 4π solid angle. In addition to the momentum of the ion from the reaction, other products like electrons or a scattered projectile can be analysed with respect to their momentum. The data obtained by this technique are fully differential in a double sense. First, for each reaction event the momenta of all particles in the final state are measured. Second, the full momentum space of all particles is covered in one experiment. In this respect such a fully-differential study includes all experiments on the particular reaction. That is in the offline analysis of the data any question concerning the final momentum states can be answered without performing a new experiment. To achieve kinematically complete information one needs to measure $3n-4$ momenta in the final state, where n is the number of particles in the continuum. The remaining 4 momenta can than be calculated from energy and momentum conservation.

For reactions with only two particles in the final state, like photo single ionization or electron capture, already the recoil-ion momentum alone gives complete information on the process. Single ionization by absorbtion of one photon is a particular simple example.

Momentum conservation requires that in the final state
